Data Supplement for Kimoto et al., Lower Expression of Glutamic Acid Decarboxylase 67 in the Prefrontal Cortex in Schizophrenia: Contribution of Altered Regulation by Zif268. Am J Psychiatry (doi: 10.1176/appi.ajp.2014.14010004)

Supplemental Methods

Tissue preparation

Frozen tissue blocks containing the middle portion of the right superior frontal sulcus were confirmed to contain prefrontal cortical area 9 using NissI-stained, cryostat tissue sections for each subject (1). For quantitative polymerase chain reaction (qPCR) studies, gray matter from adjacent sections was separately collected into a tube containing TRIzol reagent (Invitrogen, Grand Island, NY) in a manner that ensured minimal white matter contamination and excellent RNA preservation (2). Total RNA for each subject was extracted and purified with RNeasy Mini Kit (Qiagen, Valencia, CA). For *in situ* hybridization, coronal cryostat sections (20 μm) from each subject were mounted on Superfrost Plus glass slides (Fisher Scientific, Hampton, NH) and stored at -80°C until processed. Three sections from each subject, separated at anterior-posterior intervals of approximately 300 μm, were matched within subject pairs and then used to assess Zif268 mRNA expression as described previously (3).

Quantitative polymerase chain reaction (qPCR)

The difference in cycle threshold for each target transcript was calculated by subtracting the mean cycle threshold for the three internal reference transcripts (β -actin, cyclophilin A, and glyceraldehyde-3-phosphate dehydrogenase) from the mean cycle threshold of the target transcript. Because this difference in cycle threshold (Δ CT) represents the log₂-transformed expression ratio of each target transcript to the reference transcripts, the relative expression level of the target transcript is determined as 2^{- Δ CT} (4).

In situ hybridization

Tissue sections from each pair were processed side by side, and the location of the slides in the hybridization container was counterbalanced between diagnostic groups during

each run. After fixation with 4% paraformaldehyde in PBS solution, the sections were acetylated with 0.25% acetic anhydrate in 0.1 M triethanolamine/0.9% NaCl for 10 min and dehydrated with a graded alcohol series. The sections were then hybridized with ³⁵S-labeled riboprobes (1.0x10⁷ cpm/ml) in hybridization buffer at 58°C for 16 h. The hybridization buffer contained 50% formamide, 0.75 M NaCl, 20 mM 1,4-piperazine diethane sulfonic acid, pH 6.8, 10 mM EDTA, 10% dextran sulfate, 5x Denhardt's solution (0.2 mg/ml Ficoll, 0.2 mg/ml polyvinylpyrrolidone, 0.2 mg/ml BSA), 50 mM dithiothreitol, 0.2% SDS, and 100 µg/ml yeast tRNA. The sections were then washed in a solution of 0.3 M NaCl, 20 mM Tris-HCl, pH 8.0, 1 mM EDTA, pH 8.0, and 50% formamide at 65°C, treated with 20 µg/ml RNase A (Sigma-Aldrich, St Louis, MO) at 37°C, washed in 0.1x SSC (150 mM NaCl, 15 mM sodium citrate) at 68°C, dehydrated through a graded ethanol series, and air dried. Sections from both subjects in a pair, as well as ¹⁴C radioactive standards (ARC Inc., St. Louis, MO), were exposed on the same BioMax MR film (Eastman Kodak, Rochester, NY) for 4 days. After that, sections were coated with NTB2 emulsion (Eastman Kodak) diluted 3:1 with water, exposed for 35 days, developed with D-19 (Eastman Kodak) and counterstained with cresyl violet.

Film analysis of Zif268 mRNA expression

Each section was randomly coded, so that subject number and diagnosis were unknown to the rater. Autoradiographic film images were captured, digitized and analyzed using a Microcomputer Imaging Device (MCID) system (InterFocus Imaging Ltd, Cambridge, UK). Optical density (OD) was measured in the gray matter of dorsolateral prefrontal cortex (DLPFC) area 9 and expressed as nanocuries per gram of tissue (nCi/g) by reference to radioactive ¹⁴C radioactive standards exposed on the same autoradiographic film. The mean (SD) total area of gray matter sampled in each subject was 364 (169) mm² for schizophrenia subjects and 321 (158) mm² for comparison subjects.

Zif268 mRNA expression as a function of cortical layer was quantified in approximately 1-mm-wide cortical traverses extending from the pial surface to the white matter. Three cortical traverses were sampled for each section (9 traverses per subject). Each traverse was divided into 50 equal bins parallel to the pial surface and the OD was determined for each bin. These bins were then combined into six zones that approximated the laminar boundaries in the DLPFC determined in previous studies (1,5). These zones (i.e., bins 1-5, 6-10, 11-25, 26-30, 31-40, and 41-50) correspond to cortical layers 1-6, respectively. Background measures in each section were quantified within deep white matter where no specific expression of Zif268 mRNA was observed. All sampled areas for both total gray and laminar film analyses were corrected by subtracting the corresponding background measure from the same slide.

Grain counting analysis of Zif268 mRNA expression at the cellular level

Evaluation of Zif268 mRNA expression at the cellular level was performed by measuring silver grain accumulation in emulsion-dipped, Nissl-counterstained sections. Using the MCID imaging software coupled to a microscope equipped with a motor-driven stage, three 1 mmwide cortical traverses extending from the pial surface to the white matter were placed on each tissue section (9 traverses per subject). In each cortical traverse, four sampling frames (100x150 µm) were placed in layers deep 3-4, defined as 40%-60% of the distance from the pial surface to the white matter border (Figures S1A and B). The film analysis had indicated that a large difference in Zif268 mRNA expression between subjects groups was present in this location. The edges of the frame were equidistant from the border of the traverse and the edge of the next sampling frame, and the top and bottom of the frames were equidistant from the upper or lower borders of layers deep 3-4. Because RNase A treatment during the in situ hybridization procedure degrades Nissl-stainable substances within the cytoplasm, it was not possible to draw contours around the soma of neurons. Thus, the number of grains per neuron was counted within circles with a fixed size of 22 µm diameter that cover the largest crosssectional area of interneurons (~400 µm²) observed in previous studies (1). In a bright-field image of the sampling frame, the circles were centered over every Nissl-stained neuronal nucleus (Figure S1C). In a dark-field image of the same sampling frame, the number of grains

within each circle was counted (Figure S1D). Background grain density was measured in each sampling frame by using the same sampling circle to count grains over 2 glial nuclei that did not overlap with neuronal nuclei. The smaller size and intense cresyl violet staining of glial nuclei distinguished them from the larger, more faintly stained neuronal nuclei. Total neuron numbers sampled in layers deep 3-4 were 4053 and 4050 for schizophrenia and comparison subjects, respectively.

Grain density per neuron (i.e., number of grains within the 22 µm diameter circle) was calculated for all neurons and a threshold of grain density per neuron was established to identify specifically labeled neurons. For both schizophrenia and comparison groups, histograms of the grain number per neuron (log_{10} transformed) of all sampled neurons revealed a distribution that appeared bimodal, presumably representing the modes of unlabeled neurons and specifically labeled neurons (6,7). Similar histograms of only neurons with grain density $\geq 5x$ background showed a distribution that appeared normal and unimodal in both subject groups. Therefore, the threshold of $\geq 5x$ background provided a cutoff at the point of rarity in the distribution of sampled neurons and permitted the identification of specifically-labeled neurons, referred to as Zif268 mRNA positive neurons.

Figure S1: Sampling strategy for grain counting analysis of Zif268 mRNA expression

(A) Bright-field photomicrograph of a representative cortical traverse from a prefrontal cortical Nisslstained tissue section. (B) Dark-field photomicrograph of an emulsion-dipped section hybridized with an antisense ³⁵S-labeled probe for Zif268 mRNA, illustrated as accumulations of silver grains. One region of interest (large dashed rectangle) was placed across layers deep 3-4. Four 100×150 μ m sampling frames (smaller dashed rectangles) were placed in each region of interest such that the top or bottom edges of each frame were equidistant to each other and to the borders of the region of interest. (C) A representative bright-field image of a 100x150 μ m sampling frame placed in layers deep 3-4 where Nisslstained neuronal nuclei were identified and sampled within inclusion and exclusion boundaries, indicated by dotted and solid lines, respectively. Note that grain clusters identified in the dark-field image (D) are located over some of the lightly Nissl-stained neuronal nuclei in the bright-field image but not over the darkly stained glial nuclei. Circles with a diameter of 22 μ m were centered over all neuronal nuclei in every counting frame, and the number of grains in each circle was counted in the corresponding dark-field image.

Figure S2: *In situ* hybridization film analysis for Zif268 mRNA expression levels in antipsychotic medication-exposed monkeys

Representative pseudocolored film autoradiographs illustrated Zif268 mRNA expression levels in prefrontal cortex area 46 of control monkey (A), and age-, sex-, and body weight-matched monkeys chronically exposed to haloperidol (B) or olanzapine (C). Zif268 mRNA expression was measured in the gray matter regions indicated by dashed lines that correspond to area 46 around the principal sulcus (arrowheads). Solid and dotted lines indicate the pial surface and the gray/white matter border. (D) No statistically significant differences were found in Zif268 mRNA levels in monkeys chronically exposed to haloperidol or olanzapine relative to placebo ($F_{2,10}$ =0.66, p=0.54). Horizontal bars indicate group means.
