

## SUPPLEMENTARY RESULTS

### ***Consort diagram and description of MRI cohort***

**Figure S1** illustrates the selection steps for recruiting 6-9-year-old subjects for the MRI scans from the prospective cohort of 834 initially approached to participate in studies of pregnancy and infant outcomes. **Table 1** presents means and tests of significant differences for subjects in the MRI protocol and subjects eligible but not in the MRI protocol. **Table S1A** presents parametric analysis of continuous variables for the child, birth outcomes and maternal characteristics. There are no significant differences between these two cohorts of subjects for any variables compared. **Table S1B** presents means and nonparametric (Mann-Whitney U tests) tests for categorical variables. A significant difference between the groups was detected for one variable—Mother’s cohabitation status. The difference between the groups was primarily related to a higher frequency of “Neither legally married nor cohabitating with partner” in the cohort not participating in the MRI protocol. In summary, these two cohorts are virtually identical.

### ***Cortical volumes associated with total pCRH exposure across gestation***

Children exposed to high levels of pCRH throughout fetal life exhibited significant thinning of the whole cortical mantle (12%; **Table S2A**). Regional analysis indicated

that cortical thinning associated with pCRH levels was primarily observed in the temporal (15%) and the frontal (16%) regions (**Table S2A**). Neither average concentrations of pCRH across gestation nor levels at any gestational interval were associated with *increased* cortical thickness either globally or in any cortical region (**Table S2B**).

### ***Tables of FreeSurfer subregional parcellations at 19 and 31 weeks gestation***

**Tables S3** and **S4** present the percentages of FreeSurfer sub-regional parcellations associated with exposure to pCRH at 19 weeks' GA (**Table S3**) and 31 weeks' GA (**Table S4**). In **Table S3** it is apparent that the bilateral surface of the frontal regions, specifically the frontal pole is primarily thinner in children exposed to CRH at 19 weeks GA. **Table S4** illustrates a somewhat broader association between cortical thinning and later exposure to CRH. However the most striking regional association with pCRH at 31 weeks is evident bilaterally in the temporal poles.

### **Conversion to standard scores**

In order to combine the pCRH values, each raw value distribution was converted to a standard z-score distribution. Separately at 19 and 30 weeks, CRH values were converted with the formula:

$$z = \frac{(X - \mu)}{\sigma}$$

...where X is a CRH value,  $\mu$  is the population mean for CRH, and  $\sigma$  is the standard deviation.

The standard score converts CRH concentrations to a z-score distribution with a mean of 0 and a standard deviation of 1. Values for individuals are expressed in terms of standard deviations from their means. Thus a z-score of 1 indicates the subject has a CRH value that is 1 standard deviation above the mean.

### ***Analysis of logarithmic transformation of pCRH at 19 weeks gestation***

A logarithmic transformation of pCRH values at 19 weeks GA was computed to account for potential outliers. The two “outliers” were within normal physiological limits. Moreover, these women had consistently elevated levels across gestation. To perform the transform, a constant was added to the standard scores to eliminate zeros and negative numbers. (The log of a negative number is not a number and that the log of zero is negative infinity). The skewness dropped from 2.7 to 1.35. The relation between transformed CRH levels and cortical thickness for the areas in Figures 2B-D in the main text remained significant ( $r$ 's 0.26 [ $p < .025$ ]-0.39 [ $p < .01$ ]).

**Table S5** presents the FreeSurfer subregional parcellations for log transformed pCRH. The results are nearly identical with the percentages for non-transformed data in **Table S3**. The critical comparisons are highlighted.

### ***Sex Differences—Exploratory analysis***

We have reported that the age-related changes (6-9 years of age) in cortical and white matter volume (Muftuler et al, 2011; 2012) were stronger for girls than for boys. Because of the age-related differences in cortical volume, we adjusted for age at the time of testing in all the analyses reported here. The differences in the age-related changes between girls and boys prompted us to test for sex differences in

predictors and potential covariates in our cohort. As presented in **Table S6**, there were no sex differences in the predictors or potential covariates examined in this study. **Figure S2** demonstrates that patterns of association between prenatal exposure to elevated pCRH at either 19 or 31 weeks and cortical volumes differ for boys from the combined images. The patterns of association for girls exposed to elevated CRH at 19 weeks gestation differ to the combined images. In contrast, the patterns of association between prenatal exposure at 31 weeks and decreased temporal pole volume for girls are similar to the combined images.

### ***Optional Visits—Exploratory analysis***

Prenatal visits 15 (N=57) and 35 (N=55) weeks' gestational age (GA) were optional with smaller samples than the “early” and “late” cohorts. Exploratory analysis indicated that CRH exposure at 15 weeks GA was associated with significant thinning of the frontal cortex—very similar to the findings at 19 weeks GA. The significant association between pCRH and cortical thinning was bilateral but strongest in the right (19% of the structure) compared with 11% in the left frontal region. Regional analyses identified that the lateral frontal pole (40% LH and 65% RH) and the medial orbital frontal [22% LH, 33% RH] regions were the areas in which cortical thinning was most strongly associated with levels of pCRH. Pial maps depict areas of significant thinning linked with fetal pCRH exposure at 15 weeks GA and scatterplots illustrate three subregions of the frontal cortex with the strongest association (**Figure S3**). These results were highly consistent with the findings at 19 weeks GA.

### ***pCRH increases across gestation***

The human placenta synthesizes and releases CRH into the maternal and fetal circulation. Placental CRH is identical to hypothalamic CRH in structure, immunoreactivity and bioactivity (Petraglia, Sutton, & Vale, 1989; Sasaki et al., 1987, 1988). We observed the expected elevation of pCRH levels as pregnancy advanced in our cohort (**Figure S4**).

### **Correlations of *pCRH* with potential maternal, birth and child variables**

The findings from **Tables S7A-B** indicate that there are no significant associations between pCRH at 19 and 31 weeks and maternal sociodemographic and mood/anxiety indices. **Table S7C** presents data for the entire sample.

## **SUPPLEMENTAL METHODS**

### **CRH assay details**

Total CRH concentrations were determined by a radioimmunoassay with reported sensitivity of 2.04 pg/ml (RIA; Bachem Peninsula Laboratories, San Carlos, CA). Plasma samples (1-2 ml) were extracted with three volumes of ice-cold methanol, mixed, allowed to stand for 10 minutes at 4°C, and centrifuged at 1700 g and 4°C for 20 minutes (Sandman et al., 2006). Pellets were washed with 0.6 ml methanol, and the combined supernatants were dried down in a Savant SpeedVac concentrator. Reconstituted samples with assay buffer were incubated (100 µl/assay tube) with anti- CRH serum (100 µl) for 48 hours at 4°C, followed by a 24-hour

incubation with <sup>125</sup>I- CRH at 4°C. Labeled and unlabeled CRH were collected by immunoprecipitation with goat anti-rabbit IgG serum and normal rabbit serum after 90 minutes of incubation at room temperature. Samples were then centrifuged at 1700 g and 4°C for 20 minutes, after which the aspirated pellets were quantified with a gamma scintillation counter. This assay has less than 0.01% cross-reactivity with ovine CRH, 36% cross-reactivity with bovine CRH, and non-detectable reactivity with human ACTH. Intra-assay and inter- assay coefficients ranged from 5% to 15%, respectively.

### **Subjects with motion artifacts**

There were no differences between the subjects excluded because of motion artifacts and those without motion artifacts as described in Table S8 below. We also provide characteristics for the three subjects with “marginal” scans. The summary table presents mean data for the participants who completed the scan, the 7 subjects with motion artifacts and 3 subjects with “marginal” images (who were excluded from the analysis).

**TABLE S8. Data for subjects with motion artifacts in their MRI images (excluded from analysis)**

TABLE S5. Percentages of structures of the frontal and temporal lobes that are thinner in children exposed to pCRH at 19 weeks gestation using log transformed CRH values. Values can be compared with findings in Table S2. Highlights show the nearly identical results for the transformed and the z-scored data.

LH Medial Surface Frontal	Percent of Structure	RH Medial Surface Frontal	Percent of Structure
